# Longitudinally Averaged R-band Field Star Counts Across the Entire Sky 

Doug Simons<br>August 1995

## Overview

In June 1994 I acquired from John Bahcall a copy of his "export code", a FORTRAN IV program that is capable of predicting the field star density at V at any point in the sky $\boldsymbol{l} 20$ degrees from the Galactic equator. This program is based upon the well documented Bahcall-Soneira model (see Bahcall 1986, ARAA, 24, 577). Subroutine provisions built into the program make it possible to alter the output field star surface densities to various bandpasses. Accordingly I modified the code so that output at RIJHK is also possible, based upon Johnson standard star data. The extinction subroutine was also modified for these bandpasses. While the reliability of the model is certainly questionable at infrared wavelengths, it is not in serious question at submicron wavelengths for magnitudes 2020, which is roughly the point at which the Gilmore Galactic model containing a "thick disk" begins to depart significantly from the Bahcall-Soneira model.

Since the aforementioned modifications were made to the export code, the need for estimating mean field star densities, averaged across Galactic longitude, has arisen. Specifically an action was placed on me during the March 1995 A\&G/AOSWG in Victoria to produce a grid of field star densities using Bahcall's modified code, in part as a check of the fit that Rene Racine presented at that meeting which was based on color transformed V data published Allen's Astrophysical Quantities. A generalized fit to the sky also makes it easier for the various people within the Gemini Community working on AO and A\&G performance models to use a common field star model.

## All Sky Bahcall-Soneira Field Star Grid

Shown in Figure 1 is a surface plot of longitudinally averaged R-band field star density ranging from $10^{\circ}$ to $90^{\circ}$ degrees. The structure in this plot is of course dominated by faint stars at low Galactic latitudes. The greatest uncertainty in the model predictions is for low latitudes (b $220^{\circ}$ ), where variable extinction and assumptions about the structure of the Galactic disk become important in the calculations. Adopting the same basic functional form that Rene used, a 2D fit to this surface is expressed by:

$$
\begin{equation*}
\log \left(N_{R, b}\right)=\log \left(N_{R, 90}\right)+\left(\frac{b}{90}-1\right)^{2}\left(a_{0}+a_{1} R+a_{2} R^{2}\right) \tag{eq. 1}
\end{equation*}
$$

where $N_{R, b}$ is the longitudinally averaged field star density, $N_{R, 90}$ is the value at the Galactic pole, $b$ is Galactic latitude, $a_{0}$ is $-0.1, a_{1}$ is 0.10 , and $a_{2}$ is -0.0008 . To be clear, $N_{R, b}$ is the cumulative number of stars per square degree, not the number per magnitude interval. Figure 2 is the ratio of this fit to the Bahcall-Soneira grid points and

Figure 1 - The all-sky surface density grid derived from the Bahcall-Soneira export code is plotted for $10.25<R<21.25$. All values are longitudinally averaged and range from the NGP to $10^{\circ}$ latitude.

Figure 2 - The Bahcall-Soneira model shown in Figure 1 ratioed against the 2D fit expressed in equation 1. Worst case errors are $\sim 25 \%$ for a small area between $20^{\circ}<\mathrm{b}<40^{\circ}$ and $\mathrm{R}>19$ mag.
illustrates the overall accuracy of the fit. For $b$ (1) $50^{\circ}$ the 2D fit is typically accurate to within $\sim 5 \%$. The worst errors are $\sim 25 \%$ for $R$ (1) 19 and $20^{\circ}<b<40^{\circ}$. Table 1 lists the actual Bahcall-Soneira grid point values.

Figure 3 shows the all-sky average density together with a quadratic fit. The allsky averaged R-band quadratic fit derived here is:

$$
\log \left\langle N_{R}\right\rangle=a_{0}+a_{1} R+a_{2} R^{2}
$$

eq. 2
where $a_{0}$ is $-3.58673, a_{1}$ is 0.554968 , and $a_{2}$ is -0.00880835 . The error in the polynomial fit expressed in equation 2 to the mean all-sky Bahcall-Soneira model is $\sim 1 \%$. The points

| $\begin{gathered} \mathrm{R} \\ (\mathrm{mag}) \end{gathered}$ | Galactic Latitude |  |  |  |  |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | 10 | 20 | 30 | 40 | 50 | 60 | 70 | 80 | 90 |

Table 1 - Predicted longitudinally averaged field star values based upon the Bahcall-Soneira model are listed. All field star densities are per unit square degree and assume a Johnson R bandpass.
showing Rene's fit in Figure 3 corresponds to his expression at $30^{\circ}$ latitude multiplied by the Bahcall-Soneira predicted density at the North Galactic pole. Figure 3 demonstrates good agreement between the functional form used by Rene to describe the all-sky mean stellar

Figure 3 - The all-sky average is plotted (crosses) against a quadratic fit (line) explained in the text and the relation expressed by Rene Racine (solid boxes) at the March 1995 A\&G/AOSWG. In the magnitude range of interest, the scaling relation used by Rene appears to be a good fit to the Bahcall-Soneira model all-sky average. surface density and the more sophisticated BahcallSoneira prediction. For 12 < $R<20$ the difference between the fits is typically 2.5\%. It is important to note that this only represents a verification of the relative distribution of stars in the sky. The Bahcall-Soneira model significantly differs from the model used by Rene (based upon Reid and Majewski 1993, ApJ, 409, 635) in terms of absolute numbers of stars, presumably due to different $R$ bandpass definitions between the Bahcall-Soneira model and the Reid and Majewski observations.
